Abstract. The Front-End Electronics performing the ARGO RPCs readout is a full custom 8 channels GaAs circuit. About 19000 FE boards are foreseen for the experiment. We describe here the selection criteria applied by means of a systematic test devoted to check the dynamic functionality of each single channel. The statistical results from more than 20000 analysed channels are presented.

1 Introduction

The Front-End Electronics performing the ARGO RPCs readout [1][2][3] is a full custom 8 channels GaAs circuit, which integrates in a single die both the analog and digital signal processing. The die is bonded on the Front-End Board which is mounted on the pick-up strips panel and therefore completely closed inside the detector Faraday cage. This peculiarity avoids the use of interconnection cables that would degrade the analog signals transmitted to the FE Electronics. It requires however to certificate the complete functionality of the FE board before detector assembling.

2 The Electronics and the Experimental Set-Up

The Electronics global function is to amplify, discriminate and convert to ECL standard the detector signals. It is based on a three stage voltage amplifier and on a comparator with variable threshold [4],[5],[6],[7]. When dedicated to detectors working in streamer mode the chip amplification (~ 340) is too large. A resistor partition (P~ 0.15), displaced at each channel input on FE board, is applied on the input signal to attenuate the overall amplification. The block diagram with a simplified scheme of the full signal processing is sketched in figure 1.

A DC electric test is performed, before and after the bonding of the die on the board, by the involved companies. The test is devoted to check the continuity of electrical lines, the right power consumption and the correct voltage levels, in inputs and outputs, with respect to the applied voltage threshold on comparator.

An AC test is performed by the ARGO group of "Tor Vergata" University of Rome. The test checks the dynamic functionality of each single channel and selects FE boards to be assembled on the detector. It measures and registers all relevant electronics parameters to build up a complete database for the experiment.

The experimental set-up is composed by a pulse generator and a VXIbus armed with a controller VXI-MXI board interfaced with a VXI-PCI board inside an appropriate Personal Computer. A software program (BridgeView) running on the PC controls each step and performs the complete AC

leading to an 85.1 per cent yield of the FE Boards.

A window of acceptable VTH2 levels is fixed around the mean value. The greater accepted VTH2 value, corresponding in the test logic to the lowest amplification power, must be compatible with the maximum expected efficiency of the detector. Channels with good functionality but low amplification can be corrected by modifying the resistor partition at channel input.

The good or corrected channels with VTH2 values between 0.7 and 1.2 V are selected to be mounted on the detector. The distribution shown in figure 4 is the characteristic ‘response dispersion’ for these 19432 selected channels.

In figure 5 the corresponding full amplification factor of the FE electronics is shown, its mean value is 55±9. This includes the attenuation factor of 0.15 due to the input voltage divider.

The VTH2 distribution versus the eight channels of the chip, shown in figure 6, guarantees a good uniformity with respect to the threshold necessary for the full detector efficiency.

The average power consumption per channel is (22±2) mW, its distribution is shown in figure 7.

All the control parameters of the Electronics do not have any significant temperature dependence. In figure 8 are shown the scatter plots for the VTH1 voltage levels, for the VTH2 distribution and for the power consumption of the digital stage Id.
