Abstract: A probability density method for Very High Energy (VHE) γ-ray source analysis, developed using simulations and Crab Nebula data for the Whipple 10 m telescope, is presented here. Background subtraction is implemented by a modified standard approach using cuts on Hillas parameters, but the use of more complex single cut species discrimination by a kernel multivariate analysis is discussed. The probabilistic method adopted can also be extended into a log likelihood technique where data characteristics such as source strength, extension or multiple sources within the field of view can be determined.

Introduction

The work presented here is an illustrative outline of attempts to develop a complete probability density analysis method capable of detecting weak sources of VHE γ-rays with improved sensitivity. It has been developed using archival Whipple 10m telescope data [7] and Corsica simulations [5].

The method

Standard analyses in use [9] use moments of the elliptical shape produced by air shower images to produce Hillas parameters [10]. They also assume the true source location lies somewhere along the major axis of the image. The extent of the angular distance from the image centroid to the assumed origin point, $disp$, is dependant on the ellipticity of the image:

$$disp = \zeta \left( 1 - \frac{\text{width}}{\text{length}(1 + \eta \text{ leakage})} \right)$$ (1)

The additional parameter $\text{leakage}$ in equation 1 has been proposed by the HEGRA group [8] to correct for image leakage which adversely effects the ability to reconstruct source event origins accurately ¹. Image leakage is given by the total size content of pixels in the outer camera rim compared to the total image size content.

Each possible source location is smoothed with a circular Gaussian or tophat error function [9]. To investigate whether further information can be obtained by using a different error function all images taken with a point source at the center of the camera can be rotated so that their major axes lie parallel to the x-axis (fig.1 top). The resulting spread in reconstructed origins shows that on average the error function is more accurately described by an asymmetric Gaussian with the longitudinal error, $\sigma_x$, being larger than the transverse case, $\sigma_y$, by a typical 2:1 ratio as demonstrated by Gaussian fits (fig.1 bottom) to the cross-sections of the data (fig. 1 top), where $\sigma_x = 0.178 \pm 0.004$ and $\sigma_y = 0.076 \pm 0.003$. This approach verifies that discussed in [6]

Using a normalised asymmetric Gaussian, the probability density, $pg$, that the event originated from a particular bin in the field of view is given by

$$pg = \frac{1}{\sqrt{2\pi(\sigma_x^2 + \sigma_y^2)}} e^{-\frac{[ (x - x_0)^2 + (y - y_0)^2 ]}{2(\sigma_x^2 + \sigma_y^2)}}$$ (2)

¹. The leakage parameter and correction is not used in standard methods, but is included in this work.
Figure 1: Top: The excess remaining from the rotated origins of ON and OFF observed fields from Crab Nebula archival data. Bottom: Gaussian fits to the transverse (solid) and longitudinal (dotted) cross-sections given above. The asymmetric distribution of the reconstructed source origins from many events is representative of the average error function in the ability to locate a source, the longitudinal direction having a greater uncertainty.

where \( x_0 \) and \( y_0 \) are the coordinates of the reconstructed origin, and \( \sigma_x \) and \( \sigma_y \) represent the transverse and longitudinal uncertainty in location respectively.

A total 2d probability density map is then built by the superposition of all candidate events remaining from a dataset after selection. This sum is called \( P_{ON} \) for the ON (source present in field of view during observations) and \( P_{OFF} \) for the OFF fields respectively, and the significance in this work is given by

\[
\sigma = \frac{P_{ON} - P_{OFF}}{\sqrt{\text{Var}(P_{ON}) + \text{Var}(P_{OFF})}}
\]  (3)

Figure 2: Example of how the probability contours from two events are implemented to build up a 2d probability density map. The top plot uses the circular Gaussian function typical of the standard approach, whereas the lower case shows the use of an appropriate asymmetry in \( \sigma_x \) and \( \sigma_y \) applied to each event. The event centroids and major axes are indicated.

The validity of this approach has been tested and confirmed by an independent toy model described in [11].

Ideally, in the weak source case, the significance would be expected to scale with \( \text{signal}/\sqrt{\text{background}} \), leading to an upper limit improvement of \( \sqrt{2} \). The toy model has also been used to demonstrate how a probability, \( p_{\text{gamma}} \), that the candidate event is of \( \gamma \)-ray origin might be superior to the box selection cuts on Hillas parameters which previously have been shown to be very robust over a wide range of observing conditions.

Whipple 10 m image cleaning algorithms are dependent on candidate pixels having a signal to noise ratio equal to or above a given threshold. By the introduction of a total island threshold for each
Figure 3: Contour plots of the density of the rotated origins for an 11.7 hour Crab dataset where the data has been divided into two equal halves of lower sized (left) and higher sized events (middle). Contours increase from Right: Changes to $\sigma_x$ (circles) and $\sigma_y$ (triangles) with log size illustrating the changes to both the width and asymmetry of the error function.

A patch of signal in the field of view, Bond et al [2] showed using simulations that many pixels containing only background could be excluded and individual pixel S/N thresholds reduced. This work applies Island cleaning to real data and has been shown to be particularly effective for low energy events or the smaller events produced by very large zenith angle observations.

Background subtraction has been implemented in the following by applying a set of Hillas image parameter cuts evaluated for Island cleaned images by maximising for significance on the Crab Nebula. Using the above 2-dimensional probability density (2DPD) techniques, the ability to map $\gamma$-ray sources has been shown, for significance achieved, to be superior to previous methods by up to 20%.

As figure 3 shows, the ability to locate a source origin is highly energy dependant, with greater accuracy for higher (middle) to lower (left) energy events. This corresponds to a change in $\sigma_x$ (blue) and $\sigma_y$ (red) with log size as illustrated by fig. 3 right.

Table 1 gives the resulting significances and $\gamma$-ray rates for the different approaches to analysis adopted. Fig. 4 compares the standard and 2DPD methods for 11.7 hours of Crab Nebula data taken during 2003. This work is discussed in detail in [12].

Further development

The single cut approach to background selection can be implemented in various forms. Those already tested include the kernel multivariate analysis [4], the semi-analytical and 3d modeling methods used by HESS [3], and random forest techniques [1]. This work has developed a new, independant kernel analysis which, in addition to the background rejection and spectral analysis abilities demonstrated by [4], can use the resulting $\gamma$-ray probability as a weight of each event. Furthermore, since the kernel background subtraction technique allows estimation to be made of various event characteristics, the most notable being evaluation of the primary energy, then similar estimation of addi-
Dependence of the energy

Middle: comparative radial profiles of 2DPD probability density maps for different cleaning and smoothing methods over entire field. Bottom: improvement achieved over source region.

Conclusions

The 2d probability density method has been introduced and compared to standard Whipple telescope analysis and shown to be superior by up to 20% when applied to archival Crab Nebula data. The approach and application has been independently verified with a toy model. Work continues to apply the technique to candidate weak sources in the Whipple archival data, and to extend the probability density method to stereoscopic observations and survey analysis.
