Abstract: The GRAPES-3 experiment observes extensive air showers using a high-density array of scintillation detectors and a large area tracking muon detector. The showers due to charged cosmic rays could be identified by measuring their muon content using tracking muon detector. This implies that GRAPES-3 muon detector has a potential ability to distinguish primary gamma rays from a large amount of charged particles. Here we report the latest results of search for high energy gamma rays from Crab using the data of both GRAPES-3 air shower data and muon detector, which was recorded from 2000 to 2006.

Keywords: air shower, gamma ray

1 Introduction

The discovery of the pulsars in the 1960s further added to the interest in particle acceleration processes associated with supernovae, since the pulsars themselves were shown to be capable of directly accelerating particles to TeV energies and beyond. Among the many known pulsars and the associated supernova remnants, the CRAB pulsar and its associated nebula have been among the most-studied astronomical objects at all wavelengths in the electromagnetic spectrum.

Successful models for the production of γ-rays up to GeV energies, invoke the acceleration of the charged particles in the pulsar wind by the shock front to relativistic energies, and the production of the γ-rays occurs through the synchrotron and curvature radiation processes. The γ-ray energy spectrum of the CRAB nebula has been measured up to TeV energies by the pioneering observations of the Whipple group. Detailed studies on the energy spectrum in the TeV energy region by the recent high resolution imaging Čerenkov telescopes such as MAGIC, HESS and VERITAS etc., have enabled highly successful modeling of the acceleration and γ-ray generation processes occurring in the CRAB nebula. These models visualize the production of the γ-rays, through inverse Compton scattering of the synchrotron photons by the synchrotron-emitting highly relativistic electrons in the shock region. A fit to the TeV spectrum requires the acceleration of particles up to energies \( \sim 10^{15} \) eV.

It is expected that a significant part of the energy loss from the pulsar would be in the form of the hadronic component of the pulsar wind. The γ-rays produced through the decay of neutral pions (π⁰) via hadronic interactions, would have significantly different energy spectrum than the photons produced by the inverse Compton scattering from the electrons. Since the lifetime of TeV electrons in the nebular magnetic field decreases very rapidly with increasing energy, a steepening of the energy spectrum is expected in the 10-100 TeV region. On the other hand, the spectrum of the γ-rays produced via π⁰ decays may extend the energy spectrum beyond 10 TeV, without much change in the slope. Therefore, there is considerable interest, in exploring the shape of the energy spectrum in the 10-100 TeV region, in order to determine the relative contributions of these two competing processes for the production of the γ-rays in the CRAB nebula.

Here we present the results of 7-year analysis of the air showers arriving from the several known candidates of high energy gamma rays, using the muon-poor criterion for their selection as γ-ray candidate events.
2 GRAPES-3 experiment

The experimental system of the GRAPES-3 (Gamma Ray Astronomy at PeV Energy Phase-3) experiment consists of a densely packed array of scintillator detectors and a large area tracking muon detector. The EAS array consists of 257 plastic scintillator detectors shown in Fig. 1, each of 1 m² in area. These detectors are deployed with an inter-detector separation of only 8 m. The array is being operated at Ooty in south India (11.4°N, 76.7°E, 2200 m altitude).

In order to achieve the lowest possible energy threshold, a simple 3-line coincidence of detectors has been used to generate the Level-0 trigger, which acts as the fast GATE and START for the analog to digital and time to digital converters (ADCs and TDCs), respectively. As expected, this trigger selects a large number of very small and local showers and also larger showers whose cores land very far from the physical area of the array. Therefore, it is also required that at least 10 out of the inner 127 detectors should have triggered their discriminators within 1 μs of the Level-0 trigger. This Level-1 trigger with an observed EAS rate of 13 Hz is used to record the charge (ADC) and the arrival time (TDC) of the pulses from each detector [4]. The pulse charge is later converted into the equivalent number of minimum-ionizing particles (MIPS) using the most probable charge for a single MIP measured using the trigger from a small area (20×20 cm²) scintillation counter telescope.

The 560 m² GRAPES-3 muon detector [9] consists of 4 super-modules in Fig. 2, each in turn having 4 modules. Each module with a sensitive area of 35 m² consists of a total of 232 proportional counters (PRCs) arranged in 4 layers, with alternate layers placed in orthogonal directions. Two successive layers of PRCs are separated by 15 cm thick concrete. The energy threshold of 1 GeV for vertical muons, has been achieved by placing a total of 15 layers of concrete blocks (total absorber thickness ∼550 g.cm⁻²) above the Layer-1. The concrete blocks have been arranged in the shape of an inverted pyramid to provide adequate shielding up to a zenith angle of 45°.

One of the most critical parameter in the search for point sources of cosmic γ-rays, using a particle detector array is good angular resolution. This requires an accurate determination of the relative arrival time of the shower front at various detectors. The high density of the detectors in GRAPES-3 enabled an angular resolution of 0.7° to be obtained at energies as low as 30 TeV. Angular resolution of the GRAPES-3 was estimated by 2-D Gaussian fit to the Moon shadow data.

During the data period of this analysis from 2000 to 2006, GRAPES-3 air shower array keeps stable good performance mainly on the angular resolution. Fig. ?? shows the

![Figure 2: A muon station has four muon detector modules each consisting of 232 proportional counters. There are four muon stations inside the air shower array (Fig. 1).](image2)

![Figure 3: Distribution of the number of muons accompanying the observed air shower for each shower size range.](image3)

Moon shadow clearly seen in the all cosmic rays flux detected by GRAPES-3 air shower array. The Moon shadow gives us a reasonable estimation of an angular resolution of GRAPES-3 air shower array of about ∼1.1° above threshold energy.
3 Data and Analysis

The data analyzed in this study spread over a 7-year period, from 2000 to 2006. For each EAS, the core location, the shower age ‘s’ representing the steepness of the Nishimura-Kamata-Greisen (NKG) lateral distribution function and the shower size $N_e$ have been determined using the observed particle densities, following the minimization procedure discussed in detail by Tanaka et al [6]. Also, for each shower, the zenith ($\theta$) and the azimuth ($\phi$) angles have been calculated using the time information from the TDCs, also following the minimization procedure described by Tanaka et al [6].

It is very difficult to observe the tiny flux of $\gamma$-rays from various interesting astrophysical sources in the sea of nuclear cosmic rays whose direction has been randomized by the interstellar magnetic field. At higher energies, where observations have to be necessarily made with particle detector arrays at high altitudes, the muon content of showers offers itself as a possible parameter to discriminate against showers initiated by nuclear cosmic rays. Fig. 4 shows the GRAPES-3 observations on the muon content of showers. Fig. 5 shows the distribution of the number of showers in various annular regions centered on the direction of the Crab nebula for a set of data recorded 2000 - 2006, which satisfy the ‘zero-muon’ and ‘muon-poor’ criteria.

Fig. 5 shows the distribution of the number of showers in various annular regions centered on the direction of the Crab nebula from this analysis, for the shower size $N_e \geq 10^{14}$, which is corresponding the energy of about 90 TeV, satisfied the ‘zero-muon’ and ‘muon-poor’ criteria. It is interesting to note a small excess (2.1σ) flux from within 2° of the Crab nebula from a 2-D Gaussian fit to the data plotted in Fig. 5. Here we employed the angular resolution from the Moon shadow analysis which is 0.5°.

It is evident that the statistical significance of the excess from the direction of the Crab nebula for the ‘zero-muon’ and ‘muon-poor’ showers is not large and not beyond the possibility of being a statistical fluctuation. However, it is still of considerable interest to compare the observed flux with other observations at TeV-PeV energies, specially in view of the fact that the present results possibly represent the first positive detection of the gamma ray flux from the Crab nebula using the ‘zero-muon’ and ‘muon-poor’ criteria with one of the largest muon detectors used for this purpose. It may be noted here that the background flux, required for estimating the excess from the direction of the Crab nebula is rather well-determined and agrees well among the three observation regions.

In general, the integrated intensity of gamma rays from an astronomical object can be expressed as follows:

$$I = \int_{E_t}^{E_c} \frac{dN}{dE} dE$$

(1)

where $E_t$ is the effective threshold energy for detection of gamma rays with the GRAPES-3 array and $E_c$ is the assumed cut-off energy for the energy spectrum. $E_c$ is being taken to be $10^{14}$ eV here. The differential intensity can be assumed to be given by the relation:

$$\frac{dN}{dE} dE = I_0 \left( \frac{E}{E_0} \right)^{-\alpha}$$

(2)

where $\alpha$ is the power-law exponent for the spectrum in the 10-100 TeV energy range and $I_0$ is the differential intensity at a value $E_0$ for the $\gamma$-ray energy. Combining the above two equations, the integrated intensity $I$ is obtained as follows,

$$I = \int_{E_1}^{E_2} I_0 \left( \frac{E}{E_0} \right)^{-\alpha} dE$$

(3)

$$= \frac{I_0 E_0}{-\alpha + 1} \left[ \left( \frac{E_c}{E_0} \right)^{-\alpha} - \left( \frac{E_1}{E_0} \right)^{-\alpha} \right]$$

(4)

The observed flux from the Crab nebula, integrated over the time interval, between times $t_1$ and $t_2$, may be written as,
\[ I = \int_{E_t}^{E_c} \int_{t_1}^{t_2} \frac{dN}{dE} A_{eff}(E, \theta(t)) dt dE \quad (5) \]

where \( A_{eff}(E, \theta(t)) \) is the effective area of the shower array for the \( \gamma \)-ray energy \( E \) and \( \theta(t) \) is the zenith angle of the Crab Nebula at time \( t \). We adopt the same procedure for determining the flux of gamma rays from different sources in this work.

In the previous analysis of a data set from 2000 - 2004, the integral flux values have been determined for 5 values of the primary energy. For example, the integral flux above an energy threshold of 9 TeV is found to be \((5.08 \pm 2.67) \cdot 10^{-13} \text{cm}^{-2} \text{s}^{-1}\) and \((6.92 \pm 2.87) \cdot 10^{-14} \text{cm}^{-2} \text{s}^{-1}\) for energy above 30 TeV. These results are plotted in Fig. 6 for obtaining the gamma ray energy spectrum for the Crab nebula. The power-law index for the energy spectrum determined from these observations is \(1.70 \pm 0.06\) over the energy range, 9–70 TeV. In the same figure are also shown various other measurements, most of them obtained from observations with imaging atmospheric Cherenkov telescopes, except for the result from Tibet which was also based on observations with particle detector array.

It is interesting to see from Fig. 6 that a single power-law seems to fit all the measurements from ~500 GeV to energies ~100 TeV and there is no evidence to suggest any steepening of the spectrum, at least upto energy ~100 TeV.

In this analysis using the data set from 2000 to 2006, we obtained a small excess from Crab nebula in the energy of above 90 TeV. Since the amount of significance of the signal is only about 3 \( \sigma \), we couldn’t conclude that it’s the real signal from the Crab. However, it could indicate the worth trying to research the Crab in very high energy region and we will continue the study.
